A 3.5-year-old girl, the third child of a second-degree consanguineous marriage, was referred to the outpatient clinic of Children’s Medical Center with a history of skin rash, redness and recurrent abscesses (Figure 1-A). She had two apparently healthy siblings, and her family history did not disclose atopy, chronic skin diseases or any other immunological disorders. Her birth weight, height, and head circumference were in normal range, and she had reached developmental milestones as expected.

She was doing well until 6 months of age when she developed warm skin abscesses in her axillary and crural regions and also throughout her legs and hands, which were treated with oral antibiotics. The abscess fluid culture had shown Staphylococcus aureus and Escherichia coli. She later developed erythematous follicular and papular lesions with scattered blackhead comedons on both thighs, arms, armpits, and groin, along with severe and diffuse pillar keratosis. Moreover, pigmented and scaly areas with patchy appearance were distributed over her scalp, chin, and legs. We prepared the whole mount examination of her hair. It revealed a normal variant of blonde hair microscopy with normally distributed melanin in all of the samples (Figure 1-C). Normal hair shaft which is taken from healthy individual is shown in figure 1-D.

She also had documented lymphocytosis form previous complete blood counts (WBC 14,100 per µL, lymph 43% in 9 months and WBC 18,470 per µL, lymph 41.4% at the age of 2), along with a borderline positive C-reactive protein level using semiquantitative method (6 mg/l in 9 months) (Table 1). An abdominalpelvic ultrasonographic study during hospital admission in 20 months of age, had revealed mild splenomegaly (35 mm*100 mm) with numerous unspecific calcified granules of less than 3 mm in diameter, in spleen and the liver. No episode of hemophagocytic lymphohistiocytosis (HLH) had been proved for the patient prior to her workup in our clinic.

Her history of skin abscesses and abnormal skin keratinization had led to suspicion of immune dysregulation/deficiency syndromes. Allergic dermatitis was ruled out, with negative prick test and skin biopsy results. Skin biopsy and dispersion pattern of her lesions also ruled out atopic dermatitis. MPO staining ruled out myeloid malignancies of the skin. Phagocyte defects and defect in leukocyte motility had been ruled out through NBT and chemotaxis tests, respectively. Inborn keratinization defects are unlikely the diagnosis with non-diagnostic skin biopsy results. Abnormally high IgE levels with immune dysregulation and parental consanguinity raised suspect for an autosomal recessive hyper IgE syndrome (DOCK8 deficiency). Normal T-cell count, the absence of eczema, and abscesses confined to skin with no other infection sites made DOCK8 deficiency improbable (1). In the approach to her cutaneous hypopigmentation and silvery and lighter appearance of the hair shaft and associated immune dysregulations (2) in the absence of other syndromic characteristics (bleeding tendency, psychomotor findings, ectodermal dysplasia, etc.) and a suspicious history for HLH, we suspected the diagnosis of GS. Sanger sequencing of exons of the RAB27A gene (plus additional 10 bp at the exon boundaries) was performed to search for possible mutations under suspect in RAB27A gene (Griscelli syndrome, type 2), revealing only a 3′prime UTR allelic variant (A) of exon 6, rs1050931. This was a non-pathogenic heterozygous polymorphism at chromosome 15:55497691 G/A, observed in 20-34% of the normal population (3). Also, this mutation was not among recognized susceptibility loci in RAB27A, for familial HLH as part of GS type 2.

She has been scheduled on prophylactic antibiotic regiments and during her four-year follow-up in our center, has not experienced skin abscesses without any prophylactic antibiotic therapy.

Partial Oculocutaneous Albinism and Immunodeficiency (OCA-ID) refer to a group of six well-defined autosomal recessive disorders that depict combined characteristics of syndromic albinisms and recurrent infections (4). Defects in lysosomal trafficking are responsible for defective cytotoxic vesicle secretion and antigen presentation in hematopoietic/immune cell lineages and thus a propensity for recurrent infections and bleeding tendency due to platelet dysfunction in these patients. Lysosomal or extra-lysosomal defects in melanosome maturation and secretion result in partial albinism (hypopigmentation) in skin, hair, and eye (5). All three types of GS, CHS, three of the nine types of...
the Hermansky-Pudlack syndrome (HPS) and MAPBP-interacting protein deficiency, are thereby categorized as OCA-ID (4). Defective cytotoxicity in T-cells and NK-cells confer lability for chronic respiratory and cutaneous infections in all of the above syndromes. Inborn, generalized hypopigmentation is another shared feature of these OCA-ID disorders, varying in severity and clinical features between syndromes (6).

CHS and GS may be indistinguishable early in disease course with the history of patients remarkable for recurrent *Staphylococcus* infections, and the silvery-grey hair color. Majority of patients with GS experience an accelerated phase sometime between 6-12 months of age, while HLH might take up to a decade for patients with CHS to occur (6). Analysis of hair shafts either by polarized or light microscopy reveals the regular distribution of small melanin granules in patients with CHS (Figure 1-E), while the irregular pattern of melanin clumps around the hair medulla is pathognomonic for GS (Figure 1-F). No giant granule was reported in MPO staining of skin, and our patient had no ophthalmologic findings. These along with normal whole mount microscopic examination of the hair shaft lowered potentials for CHS to be the diagnosis. Neurological features, as happen with late-onset neuropathies, balance disturbance and cognitive decline in CHS are rare in GS and usually associate with the accelerated phase of HLH.

HPS type 2 and 9 are recognizable from CHS and GS with clinical features of ocular hypopigmentation at birth including nystagmus, iris trans-illumination, and low visual acuity. In contrast, skin and hair color tone is variable in patients with HPS and HLH is rare in these patients.

Among the three types of GS, GS type 1 depicts only primary neurological deficits along with hypopigmentation and no immune dysregulation, while GS type 3 is solely characterized by skin and hair hypopigmentation (6). Based on patients history of recurrent skin abscesses, the absence of severe bleeding diathesis and the OCA-ID our patient was likely to have CHS or GS type 2.

GS type 2 is the result of defective Rab27a protein. Mutations in RAB27A that affect its binding sites to GTP, Myosin 5a or MUNC 13-4, have shown pathogenic relevance to GS type 2 (7,8). What made GS type 2 a suspicious diagnosis for this patients was the vague history of HLH and absence of any accelerated phase until 3.5 years. Her lab data suggested mildly elevated ANC count, lymphocytosis and no thrombocytopenia, inconsistent with the HLH (9).

Although most GS type 2 patients experience HLH syndrome, the absence of clinical HLH episodes does not rule out the diagnosis of GS, as some mutations selectively destruct the MUNC 13-4 binding site, conserving the GTPase activity of RAB27A (10). Some episodes of HLH might go undetected or present with self-limiting and mild symptoms in patients (11).

Given high IgE levels, parent consanguinity and a history of skin abscess with *S. aureus* and chronic eczema, the diagnosis of autosomal recessive hyper IgE syndrome was also postulated. The diagnosis of hyper-Immune globulin E syndrome (HIES) remained highly suspected before we ruled combined immune deficiencies associated with DOCK8. Although IgE usually peaks above 2000 IU/ml in patients with HIES (12), most patients with isolated IgE above 2000 IU/ml do not have HIES (13).

Approach to syndromic albinisms will be hard especially in children of Caucasian origin with natural blonde hair. Analysis of the hair shaft by light or polarized microscopy could be beneficial for earlier identification of the disorder and timely initiation of treatment in suspicious patients with syndromic albinism. The pitfall here is that we may face normal hair pigmentation as observed in our patient. Normal heterozygous variant in RAB27a also could not help the diagnosis.

As we have faced a diagnostic dilemma in this patient, whole genome sequencing might be a good approach to detect underlying gene defect in this patient.
